Abstract. As computing and geophysical sensor components have become increasingly affordable over the past decade, it is now possible to design and build a cost-effective system for monitoring the Earth's natural magnetic field variations, in particular for space weather events. Modern fluxgate magnetometers are sensitive down to the sub-nanotesla (nT) level, which far exceeds the level of accuracy required to detect very small variations of the external magnetic field. When the popular Raspberry Pi single-board computer is combined with a suitable digitiser it can be used as a low-cost data logger. We adapted off-the-shelf components to design a magnetometer system for schools and developed bespoke Python software to build a network of low-cost magnetometers across the UK. We describe the system and software and how it was deployed to schools around the UK. In addition, we show the results recorded by the system from one of the largest geomagnetic storms of the current solar cycle.

1 Introduction

Over the past decade, the introduction of cheap reliable computing hardware and sensors, along with the ubiquity of high-speed Internet connections, mean that it is now possible to create low-cost open-science networks of geophysical sensors. This has encouraged the development of data-intensive networks, for example in climate studies (Weather Observation Website: <https://www.metoffice.gov.uk/>, last access: 8 October 2018), seismology (BGS School Seismology Project: <http://www.bgs.ac.uk/schoolseismology/>, last access: 8 October 2018) or cosmic ray research (the TimPix Project: <http://www.researchinschools.org/TIMPIX/home.html>, last access: 8 October 2018), where spatial and temporal gaps in the professional scientific networks may

be filled or augmented. Some networks employ existing platforms such as mobile phones using in-built sensors to record data (e.g. CrowdMag, see <https://www.ngdc.noaa.gov/geomag/crowdmag.shtml>, last access: 8 October 2018) while others create bespoke hardware with higher accuracy than general-purpose systems. In geomagnetism, high-quality low-cost fluxgate sensors have become widely available, allowing accurate monitoring of the variation of the Earth's magnetic field over time ranges of several minutes to hours. This prompted us to investigate the various types of commercial sensors and their ability to monitor the external magnetic field, and in particular their ability to record large geomagnetic storms.

The Raspberry Pi is a small single-board computer that typically runs the Linux operating system. Peripherals such as sensors may be directly connected to its general purpose input–output (GPIO) pins. Relatively cheap fluxgate magnetometer sensors are now available from a number of suppliers and analog-to-digital converters are also commonplace in the Raspberry Pi ecosystem. For around 1/100 of the price of a conventional scientific-standard fluxgate magnetometer instrument we found that we could build a system with approximately 1/100 the accuracy and resolution. (At 2018 prices, the Raspberry Pi magnetometer costs around GBP 150.) Despite the lower accuracy, this is still easily sufficient to record the daily variation of the Earth's ionosphere and magnetosphere, in order to detect the rapid changes in the magnetic field during geomagnetic storms. As a combination of a citizen science experiment and an outreach and education programme in geophysics, we applied to the UK Science Technology and Facilities Council (STFC) in 2015 for a Small Public Engagement grant and were successful. In the application we bid for funding to build and deploy 10 systems to schools across the United Kingdom.

In Sect. 2 of this paper we briefly describe the science of the magnetic field and what a sensor measurement consists of. In Sects. 3 and 4 we outline how our system works and was deployed to create a school network. As an example of its utility for science, in Sect. 5 we show the results of combining the Raspberry Pi magnetometer network with measurements from the permanent magnetic observatory network in the UK to enhance our understanding of the spatial and temporal dynamics of a large geomagnetic storm on 7–8 September 2017. Finally, we discuss some of the lessons learned from the project in terms of public engagement and interacting with schools.

2 The Earth's magnetic field

The Earth's magnetic field is a vector quantity with a strength and direction, which varies both in time and space (e.g. Merrill et al., 1996). It has an average strength on the surface of around 50 000 nT, though this varies from 20 000 nT at the equator to 65 000 nT at the poles. Though the field is strong enough to move a small iron needle, it is, in fact, incredibly weak; a standard fridge magnet is tens to hundreds of times stronger.

After temperature measurements, the magnetic field has one of the longest observational records available, dating back centuries (Jackson et al., 2000). The vast majority (> 95 %) of the magnetic field is generated in the liquid iron outer core by the self-exciting geodynamo. Similar to a bicycle dynamo, the Earth's outer core converts energy from motion of the conductive liquid iron into electrical currents. However, unlike a bicycle dynamo, the core is far too hot (> 3500 K) to be permanently magnetised (e.g. Lowrie, 2007). The electrical currents in the core generate a long-lived magnetic field which is detectable on the surface of the Earth. In addition, remnant magnetisation of iron-bearing minerals in the upper crust act as another internal source but are small on average compared to the core field (typically < 1 %). The remaining magnetic sources are external to the Earth's surface and include currents flowing in the conductive ionosphere (at altitudes of 100–1000 km) and in the large-scale magnetosphere created by the interaction of the Earth's magnetic field with the conductive solar wind. External fields are generally small (< 4 %) but can rise locally to over 10 % of the field strength at high latitudes during large geomagnetic storms (e.g. Kivelson and Russell, 1995).

When a measurement of the magnetic field is made on or above the surface of the Earth, the value obtained is the sum of all sources. Each source has a distinct temporal and spatial behaviour and, by measuring the field and its variation in many different places over time, the observations can be used to understand the individual geophysical systems. The crustal magnetic field changes on the slowest of timescales – tens of millions of years on average. The core field changes on periods of around 1 year to millions of years, which in-

cludes global magnetic field reversals. The ionospheric magnetic field changes on a diurnal basis, driven by the effects of solar illumination and seasonal dependence on the solar elevation angle. Finally, the magnetospheric field varies on timescales of seconds to days. On days without obvious magnetic activity, the solar wind loads the magnetosphere with energy over the course of several hours. This causes small “substorms” to form in the polar regions through a process called the Dungey cycle (Dungey, 1961).

Occasionally, when magnetic activity on the Sun's surface increases, for example from a coronal mass ejection (CME), the speed and density of the solar wind (the tenuous ionised “gas” which permeates the space between the planets) increases and the interplanetary magnetic field is perturbed, resulting in energy being passed into the magnetosphere and ionosphere and causing large electrical currents to flow in the upper atmosphere. When this happens, intense auroral electrojets form, move from their usual position near the poles and expand toward the equator, generating relatively large magnetic fields (100–1000 nT) which can be detected on the ground. The magnetosphere becomes loaded with energy which it attempts to dissipate every few hours through a process called magnetic reconnection. This causes the magnetic field to vibrate or pulsate at certain frequencies. These “pulsations” last from a few seconds to tens of minutes and can be readily measured on the ground.

As most of the source signals overlap in time and space, they are difficult to identify with a single measurement. Hence, we need many sensors in a large network running for a long time in many different locations to resolve the contribution of each source. The global scientific magnetic observatory network fulfils this role. These are sites chosen specifically to reduce disturbance from man-made electrical or magnetic noise and hence tend to be in rural locations away from cities and railways. However, there are presently only around 200 magnetic observatories worldwide, with a very uneven spatial coverage biased towards the Northern Hemisphere, and Europe in particular (Love and Chulliat, 2013). Data are freely available from most of these observatories on the INTERMAGNET website (<http://www.intermagnet.org/>, last access: 8 October 2018).

Magnetic field measurements

The geomagnetic field can be measured with an instrument known as a magnetometer. There are several types of instruments that can be used to make a measurement such as (a) a simple compass needle to measure angles, (b) a copper wire wound around a cylinder of iron known as a flux-gate magnetometer to measure strength in a particular direction or (c) a magneto-resistive etching on a silicon chip (as in mobile electronic devices), again able to measure directional strength. The type of instrumentation used in scientific observatories has evolved over the past century from, essentially, compass needles suspended on quartz fibres requiring

manual intervention to modern automated fluxgate magnetometers harnessed to digital electronics.

For our systems we use fluxgate magnetometers, which consist of a small cylinder of magnetisable iron wrapped by a copper wire with a large number of turnings (Primdahl, 1979). An electrical current, controlled by an oscillator, is passed backward and forward through the copper wire, creating a magnetic field. The magnetic field from the electrical current magnetises the core in one direction along its axis, then in the opposite direction. If a pre-existing magnetic field exists in the environment, such as the Earth's magnetic field, then it requires less current to magnetise the core along that direction. The current difference is directly proportional to the strength of the pre-existing magnetic field, meaning that fluxgate sensors can be calibrated to relate current to magnetic field strength. Thus, a calibrated standard fluxgate sensor can measure the strength of the magnetic field along the direction of its axis and is sufficiently sensitive to the absolute level and variations down to the 1 Hz range of the field. The main drawback of fluxgates are their sensitivity to temperature change.

To measure the full magnetic field (as the magnetic field is a vector which has a strength and direction), three fluxgate coils set at right angles to each other are used. The convention (in geomagnetism) is to use an orthogonal Cartesian coordinate system (X , Y and Z) where the X axis points toward geographical north in the horizontal plane, the Y axis points to geographical east and the Z axis points down towards the centre of the Earth. Thus, the strength and direction of a magnetic "field line" passing through the sensor can be measured by how strong it is in each component. From the measurements of magnetic field strength made along each axis, a full set of all magnetic components can be calculated, which may also be expressed as the declination (D) and inclination (I) angles and the strength of the horizontal (H) and total (F) field. Our system is a variometer which can only provide approximate values of the strength and the relative change of the field, compared to scientific observatories which make highly calibrated absolute measurements of the geomagnetic vector and strength (Reda et al., 2011).

3 Instrumentation: development and build

The Raspberry Pi school magnetometer system consists of (a) a sensor head which has three fluxgate magnetometers and (b) a Raspberry Pi computer with an separate internal analogue-to-digital converter (ADC) board. The sensor head is linked to the ADC board via a connecting wire. Both the board and the magnetometers are powered by the Raspberry Pi. A blue LED within the sensor head indicates that the system is receiving power (Fig. 1). The FLC100 magnetometers (from Stefan Mayer Instruments, Germany) are extremely sensitive to small variations of the magnetic field, with an operating range of zero to around 100 000 nT.

As noted, a standard magnetic field sensor has three magnetometers which are orientated along the three orthogonal components: north (X), east (Y) and down (Z). The fluxgate coils are mounted in a Perspex block with a plastic base and brass screws (which are all non-magnetic). The sensor head also has a thermometer to measure the ambient temperature of the air. As it is so sensitive to temperature change, the system should ideally be kept at a constant temperature. A cover prevents accidental physical damage and helps reduce the rate of temperature changes to which the sensors are exposed.

The fluxgate magnetometers have been calibrated to output a 1 V analogue signal for a magnetic field strength of 50 000 nT. The analogue voltage is converted into a digital signal by the ADC. The 17-bit ADC is connected to the Raspberry Pi's Inter-Integrated Circuit (I²C) bus using the GPIO pins. A cable connects the three fluxgate coils and the temperature to the ADC. The analogue signals are wired as single-ended inputs and so cannot make use of the 17th signed bit, giving the system a digitisation resolution of $2^{16} = 65\,536$ levels. Hence, the digitiser has a finite resolution which inherently limits the precision of the magnetometer.

As an example, the smallest resolution is $50\,000\text{ nT}/65\,536 = 0.76\text{ nT}$, meaning the digitiser can only resolve a magnetic field change larger than 0.76 nT. However, if the magnetic field strength is reduced to 15 000 nT, then the resolution increases, i.e. $15\,000\text{ nT}/65\,536 = 0.22\text{ nT}$. In practice, there are various factors that limit the resolution of the system so that the true precision is around 1.5 nT. This is sufficient to detect all the external field phenomena that are of interest to us.

To make a magnetic field measurement, the ADC samples the voltage several times a second and then the Raspberry Pi averages the values measured over 5 or 10 s. Taking the average of a number of measurements has the effect of smoothing out the variation (from temperature changes, electronic noise and changes in the magnetic field) to give a mean value of the magnetic field over the short period. The Raspberry Pi is not fitted with a real-time clock and therefore it is important that it is connected to the internet in order to obtain and keep the correct time. The clock drift is on the order of several seconds per day, so a Network Time Protocol (NTP) server is polled every two minutes as part of the computer's routine job schedule. An internet connection is also required for the transfer of magnetic field data to our remote server.

Operation and testing

Our magnetometer system was designed to measure the external field variation rather than the core field. Although it also measures the strength and direction of the Earth's full magnetic field vector, the instrument is not stable enough over the long term (i.e. days to weeks) to be a useful instrument for studying main field changes. As well as tempera-

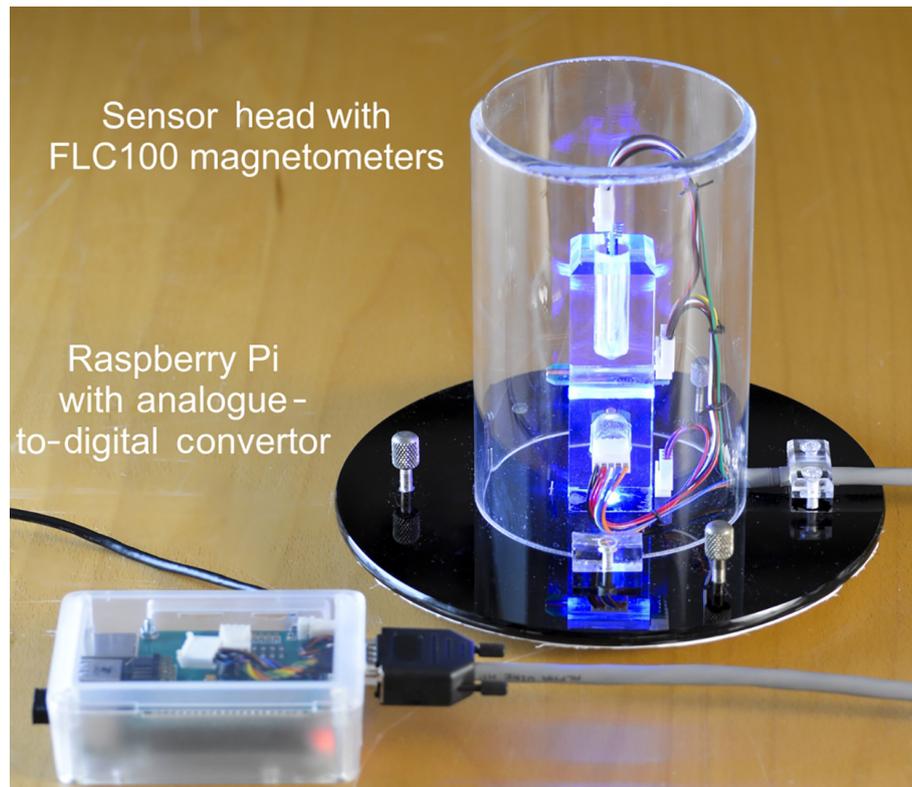

Figure 1. Raspberry Pi magnetometer system: the computer and digitiser board are in the small box in the lower left corner (enclosed in a transparent plastic box). The sensor head contains three orthogonal fluxgate sensors in the Perspex cube, again contained in a transparent case, which are connected by wires via the gray cable to the digitiser. A blue LED provides illumination to indicate the system is powered on. The thermistor is located at the base of the sensor (not visible). Brass feet and a bubble spirit-level embedded in the base are used to ensure the fluxgates are not tilted. The sensor head is approximately 15 cm high.

ture, the magnetometer is also sensitive to man-made magnetic fields from mobile phones, vehicles or lifts in a building, for example. Consequently, we usually disregard the full field measurements and compute the variation of the horizontal field ($H = \sqrt{X^2 + Y^2}$) around a quiet-time value, usually considered to be around 02:00–03:00 LT (local time).

We tested an initial prototype, placing it in an unused office at the British Geological Survey (BGS) building in Edinburgh, over several months in 2014 and compared its results to the data from the closest geomagnetic observatory in Eskdalemuir, Scotland. Figure 2 shows an example of 6 days of data recorded on the Raspberry Pi magnetometer in Edinburgh. The horizontal strength (H) was computed and the average value for the period was subtracted from the result to give the variation. The blue line shows the data from the Raspberry Pi. For comparison, the data recorded on a scientific instrument (called Geomagnetic Data Acquisition System or GDAS1) at the Eskdalemuir Observatory approximately 70 km to the south of Edinburgh are shown in black. The data from the Edinburgh system closely match the variation recorded at the observatory.

A number of different geomagnetic events were observed. On 12 September there was a geomagnetic storm which

caused the magnetic field to fluctuate from +125 to –125 nT. The storm ended on 13 September when the variations became smaller. The storm was followed by a series of smaller rapid wiggles (pulsations) which are the result of dissipation of energy from the magnetosphere. By 14 September, these disappeared and the ionospheric solar quiet-time (Sq) current became visible. This is seen as a daily fall and rise of about 20 nT, with its lowest point at noon when the Sun passes overhead, on 15, 16 and 17 September. Finally, on 17 September there is a step down and then up during the day time. This is man-made, caused by someone changing the magnetic environment of the room (e.g. entering the room for a time and then leaving later in the day).

Further testing of the second iteration of the sensor design was carried out in late 2015. The updated magnetometer system was fitted with a solid-state temperature sensor and was deployed in Eskdalemuir for several weeks. It was placed in a non-temperature-controlled building around 100 m from the GDAS1 system. Figure 3a–b show the variation of the horizontal and vertical components compared to the Eskdalemuir GDAS1 system. Panel (c) shows the difference between the two systems, with the temperature plotted too. There is a strong correlation between the magnetic differences of the

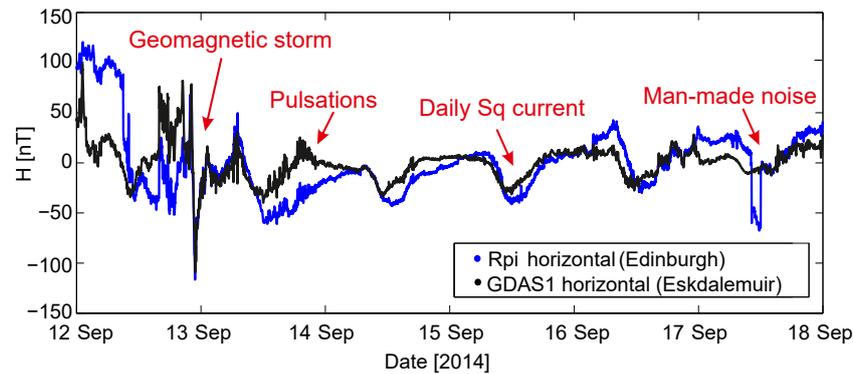

Figure 2. Horizontal field variation from 12 to 18 September 2014. The blue line shows data from the Raspberry Pi magnetometer located in Edinburgh, UK. The black line is from the BGS GDAS1 system in the Eskdalemuir Geomagnetic Observatory (70 km south of Edinburgh).

Raspberry Pi systems and the temperature changes recorded. The step during 30 October is due to manual retrieval of the data, affecting the room temperature temporarily. However, though the systems are very temperature-dependent, it is possible to remove much of the error by “backing-out” the measured temperature variation through calibration. We demonstrate this using a second-order polynomial model to compute the least-squares best-fit coefficients between the magnetometer differences in each component (H and Z) and temperature variation. These model fits are also shown in Fig. 3, denoted by “corrected”. The linear coefficients are of the order of $3.8 \text{ nT}^\circ\text{C}^{-1}$ for the H component and $12.7 \text{ nT}^\circ\text{C}^{-1}$ for the Z component. Table 1 gives all six coefficients.

Overall these tests indicate that, provided the Raspberry Pi magnetometer system is kept in a magnetically quiet and stable temperature environment, it is quite capable of capturing genuine geophysical phenomena, including the geomagnetic storms in which we are most interested.

4 Deploying the network

In order to promote the new magnetometers, we attended a number of professional development events run for secondary-level physics teachers to recruit potential schools around the UK. We also used contacts in the Institute of Physics and personal connections to find teachers who were interested in hosting a magnetometer at their school.

As noted, on its own a single magnetic sensor system is not particularly useful, but it can provide an educational tool for physics, astronomy, geology and geography students. However, tied into a UK-wide network of sensors, it is a means to participate in a genuine scientific collaboration to study the detailed variation of the magnetic field over the UK, particularly during geomagnetic storms. This is the “pitch” we used to encourage teachers to host a system at their school. We provided an explanation of the science and tutorial notes for the teachers and pupils to read. We also suggested ideas of

Table 1. Correction coefficients for the temperature dependence in Fig. 3.

Component	Offset (nT)	Linear ($\text{nT}^\circ\text{C}^{-1}$)	Second-order ($\text{nT}^\circ\text{C}^{-2}$)
Horizontal	-1.53	3.85	-0.16
Vertical	0.63	12.68	2.27

how to use the data, including how to process it using Jupyter notebooks and Python scripts.

After our initial building and testing phases, we further developed the Python logging software to run the system automatically and pass the data back to the Internet. We sought to make the system as easy as possible to set up on site. To that end, the Raspberry Pi magnetometer software was set to start logging magnetic field data as soon as it is switched on. The system saves the outputs from the sensors to a file, containing the X - Y - Z magnetic field (in nT) and the temperature at the sensor head (in $^\circ\text{C}$). The data are recorded every 10 s and placed into a comma-separated value (.csv) file which can be read by Excel, Word or any other type of data processing software. The data are written to a particular directory on the Raspberry Pi which can be found under `/data/bgs_sch/<site_name>/<Year>/<Month>/<site_name_YearMonthDay.csv>`

Two other files may also be created each day: a logging file (.log) and a bad data file (.csv.bad). The logging file has information about when the logging of data starts and ends. If there are problems with accessing the internet or time from an NTP server then data are written to the .csv.bad file instead to indicate there are uncertainties in the time record. Once every 5 min a Linux “cron” job runs on the Raspberry Pi to transfer the recently recorded data to the Lancaster University website. Real-time plots of the data can be viewed at <https://aurorawatch.lancs.ac.uk/plots/>. The data may also be accessed from the Raspberry Pi directly.

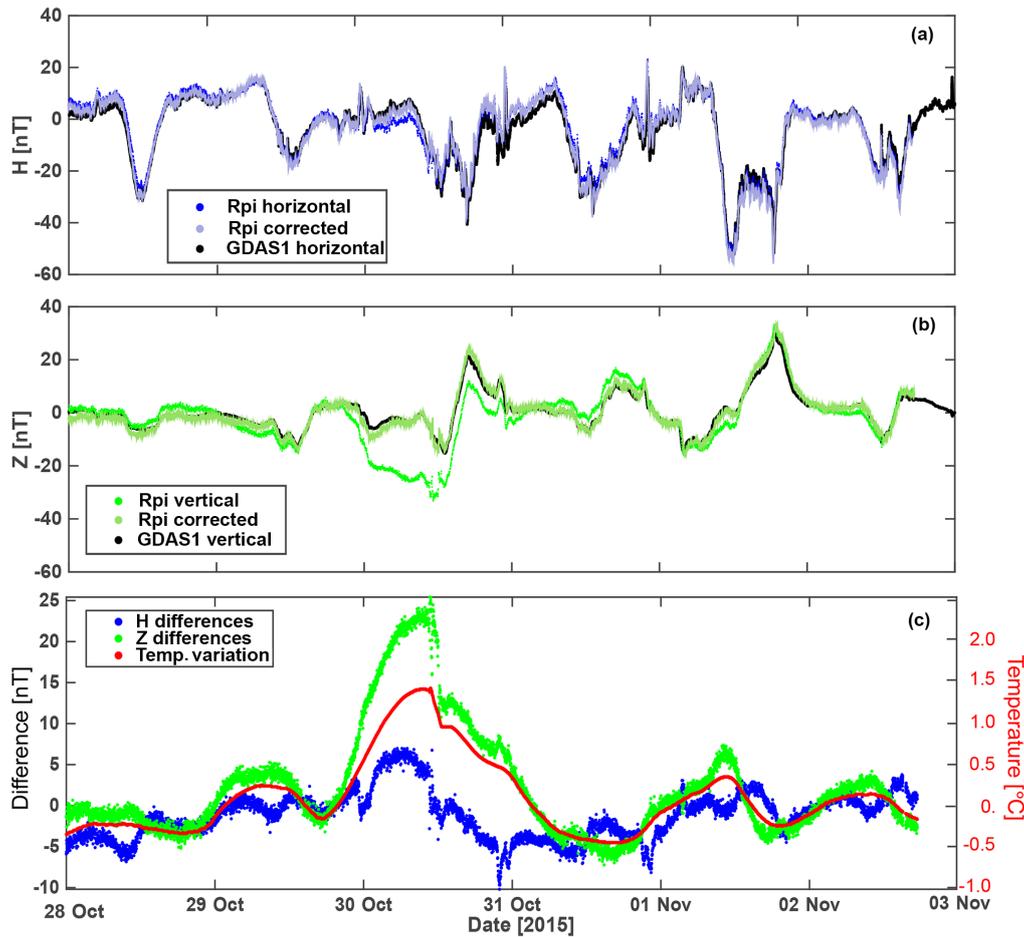

Figure 3. Comparison of the magnetic field variation between the Raspberry Pi magnetometer and Eskdalemuir GDAS1 system from 28 October to 3 November 2015. (a) Horizontal component variation and temperature-corrected data. (b) Vertical component variation and temperature-corrected data. (c) Difference between the Raspberry Pi and GDAS1 systems, and temperature variation around a baseline value of 18 °C.

It took over a year to deploy most of the sensors. Figure 4 shows the final destinations of nine of the Raspberry Pi magnetometer systems across the UK. The aim was to cover the UK in both latitude and longitude and to complement the ex-

isting BGS and Lancaster networks. Benbecula in the Outer Hebrides is the most northerly and westerly point, Norwich is the most easterly point and Eastbourne is the most southerly point in the network. There is a cluster around Birmingham

to tie in with a University of Birmingham cosmic ray experiment running at the Physics Department and in two local schools (Bordesley and King Edward's). Table 2 gives the locations of each sensor. One of the systems was sent to the University of Otago in Dunedin, New Zealand, as an experiment to show how the magnetic field varies simultaneously on a global basis during a geomagnetic storm. New Zealand is at the same absolute geomagnetic latitude as the UK in the Southern Hemisphere.

The first system began running in October 2016 and the network expanded over 2016 and 2017. In the next section, we show an example of a major storm which was captured by the magnetometers.

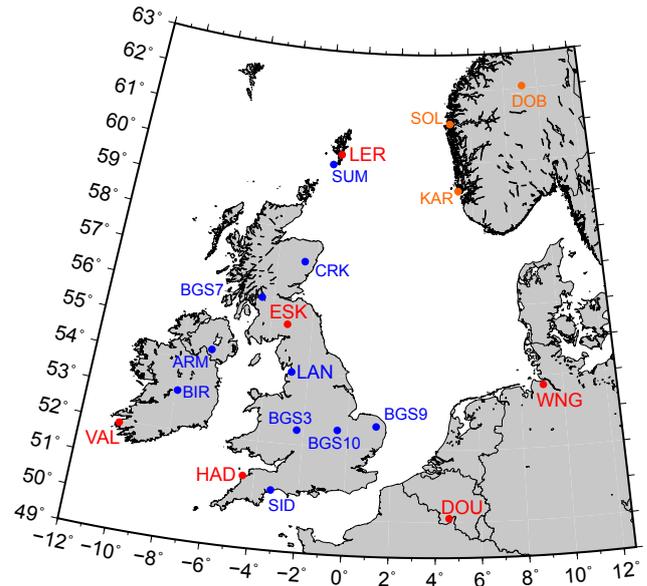

Figure 5. Map showing the locations of the variometer and observatory measurement sites available for 7–8 September 2017. Red circles are INTERMAGNET observatories, orange circles indicated calibrated variometers (TGO) and blue indicate variometers including the Raspberry Pi (BGS) and the Lancaster AuroraWatch/SAMNET/MagIE magnetometers.

5 Measurements from the geomagnetic storm of September 2017

In September 2017 one of the largest storms of the current solar cycle hit the Earth. A CME left the Sun at midday on 6 September and reached Earth's magnetosphere in around 36 h. Starting around 23:30 UT on 7 September, the first and deepest part of the storm lasted for around 3 h. Beautiful aurorae were visible all across the UK. Around 13:00 UT on 8 September a second burst arrived, though as it was during the day in the UK, the aurorae were not visible. The magnetic signature was detected by the Raspberry Pi magnetometer network. As the north (or X) direction is most sensitive to the auroral electrojet (which are created by east–west directed ionospheric electric current flows), we focus on this component in the plots shown.

To get a regional picture of the storm, data were collected from the Raspberry Pi magnetometers, as well as a number of other variometers and observatories around the UK, Ireland, Belgium, Germany and Norway. Figure 5 shows the location of the scientific observatories (INTERMAGNET), the BGS and Lancaster University AuroraWatch network of variometers (Case et al., 2017), a network in Ireland run by Trinity College Dublin (MagIE), and data from the Tromsø Geophysical Observatory (TGO) network.

The data were processed to remove the quiet-time mean value of the X component at each site, using the value for 02:00–03:00 LT from 7 September. Where the orientation of

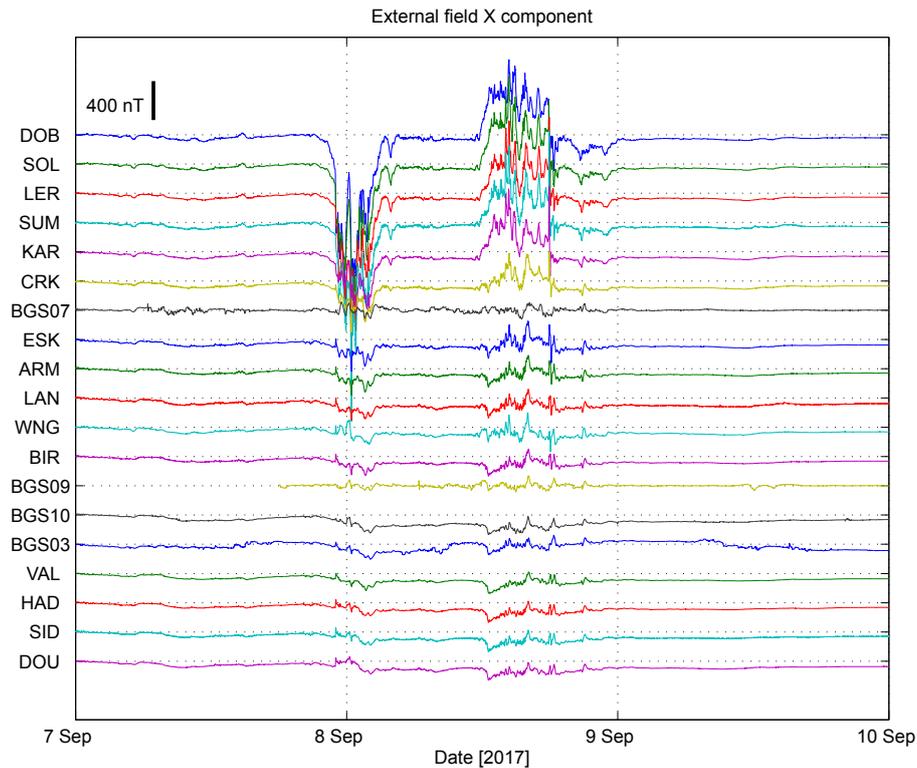

Figure 6. Stack plot of the variation of the X component over time at each measurement site from 00:00 UT on 7 September to 00:00 UT on 10 September. Stations are ordered by geographic latitude. Note the initiation of the storm at midnight of 7–8 September and the second phase beginning at 12:00 UT on 8 September. Scale bar denotes 400 nT change.

the sensor is unknown (as with the Raspberry Pi magnetometers) we rotated the horizontal components to match the estimated values of X and Y from a global magnetic field model (the International Geomagnetic Reference Field version 12; Thébaud et al., 2015). In Fig. 6, we show the change of the magnetic field over the 3 days covering 7–9 September 2017. The observatories and variometers are arranged by geographic latitude. The first and second parts of the storm are clearly visible as large spikes in the northern stations, decreasing in intensity further south. This is the signature of the auroral oval moving south during the peak of the storm, then returning northwards. In the first burst of the geomagnetic storm, the magnetic signature of the aurora moves as far south as LER and SUM, which are in the Shetland Islands. The Raspberry Pi data (BGS nn) complement the other variometer and observatory data, matching the magnitude and timing of the main phases of the storm though they are slightly noisier overall. Sadly, not all system data were available at the time, so we did not completely cover the UK (e.g. Benbecula and Eastbourne are missing).

The line plot data were turned into a map of the magnetic field variation across the UK for each minute, interpolated using a physics-based method called spherical elementary currents (Amm and Viljanen, 1999). Figure 7 gives a snapshot of the X and Y external magnetic field components at

23:45 UT as the auroral electrojet moves southward across the UK. It extends south of Shetland, as can be observed most clearly in the X component (left panel). A video of the storm can be seen at <https://youtu.be/ueDvVNHnNbIc> (last access: 8 October 2018). In the video, several more bursts of activity can be seen later in the day between 12:00 and 18:00 UT. Without the new magnetometers, it would not be possible to distinguish such detail. These measurements will lead to a better understanding of how the magnetic field changes over regions smaller than 1000 km during large geomagnetic storms at mid-latitudes.

6 Lessons learned

The idea of a school magnetometer network was inspired by the long-running UK School Seismometer network, part-run by BGS. Having experimented with the Raspberry Pi, it was an obvious and capable device for attaching to all manner of sensors. As with most projects, the concept and initial ideas of how it might work and operate differed strongly to the end results. After making a prototype sensor and then bidding for a larger grant to make 10 systems, we found that the building and development of the hardware and software was the (relatively) easy part – after all, this is what we do professionally.

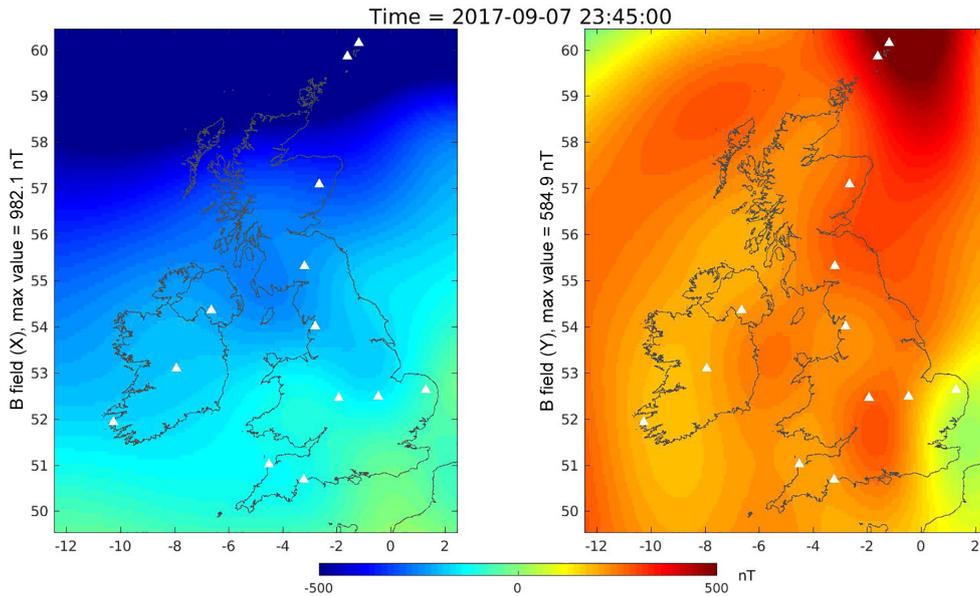

Figure 7. Snapshot of the two horizontal components of the magnetic field interpolated across the UK at 23:45 UT on 7 September 2017.

However, once the systems were built, the harder parts of the project were the actual engagement with the schools and deploying the systems out to them. For half of the schools, we personally delivered the systems and helped to set them up. Schools are busy places though and it is difficult to get a teacher's time and to hold their attention for more than a few hours. More surprising was how tightly controlled school Wi-Fi or Ethernet networks are. In fact, much of the set-up time was spent attempting to gain access to an open internet connection within the school. Many of the schools were unable to continuously meet the magnetically quiet environment criterion, making stable measurements (without steps or temperature drift) over a single day hard to achieve during the working school week. Some of the schools managed to place the sensor in a quiet location but this reduces the opportunity for students to observe the system or to notice it on a daily basis. Finally, once deployed, we found getting feedback from the teachers and schools was relatively slow. As the teachers rotate through different year classes after each term, the systems become unplugged or moved to noisier environments, which further degrades their scientific usefulness. Hence, we monitor the data regularly and will contact the school to check if the data become poor or unusable.

Unfortunately, there are no easy ways to combat many of these issues – they are a function of the way schools operate. However, we hope at least some students have been inspired to consider geophysics as a future career based on their interaction with the sensors and data.

7 Conclusions

We have developed a Raspberry Pi magnetometer system using standard off-the-shelf sensors and materials. The system costs around 100 times less than a scientific-grade sensor (around GBP 150 in 2018), but is sufficiently accurate to detect external magnetic field changes (at the nanotesla level) from geomagnetic storms. We describe the build, testing and deployment of systems to schools around the UK to create a countrywide network. We also offer an example of how the data can be used to supplement the existing network of scientific observatories and analyse a large geomagnetic storm on 7–8 September 2017. This is an excellent example of how falling hardware costs in combination with science outreach can provide an interesting geophysical sensor network which can be used for both science and education.

Code and data availability. Data are freely available from the Lancaster University AuroraWatch data catalogue at <https://aurorawatch.lancs.ac.uk/data/> (AuroraWatch UK, 2018). Code for running the magnetometer is freely available from Steve Marple's repository on GitHub at <https://github.com/stevemarple/> (Marple, 2018). Instructions for building the hardware can be obtained by contacting the corresponding author.

Author contributions. CDB built, integrated and tested much of the hardware. SRM developed the software to run the systems and transfer the magnetic data to the AuroraWatch UK website. Both contributed to the writing of the paper.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We wish to thank the STFC for awarding a Small Public Engagement Grant in 2015 (ST/M006565/1) which made this work possible. We acknowledge the support and collaboration of Farideh Honary (Lancaster University) on this project. We thank the schools, teachers and technicians who helped to install and run the magnetometers on site. We also thank Tim Taylor, Tony Swan and Ted Harris at BGS for their support in building and testing the magnetometers before deployment and Sarah Reay for reviewing the paper. Finally, we thank the five reviewers and one commentator who made useful suggestions for improving the figures and the text of the paper during the review and discussion phase. This paper is published with the permission of the Executive Director of the British Geological Survey (UKRI).
